## 1 A program for Defining 2-D Geometries

This program began as an extension and generalization of the logic used in *readgeometry*. The approach used has been rather successful, permitting a wide variety of geometries to be described in a straightforward manner. While the code can be run using just a human generated text input file, with perhaps some auxiliary data in other text files, truly complicated cases can be handled when the code is run in conjunction with other geometry packages.

For coupling to codes using a structured, quadrilateral mesh, one can take advantage of the interface to the DG code, developed in Garching, that gives the user what is effectively a GUI for the problem at hand. Alternatively, the plasma mesh used by the UEDGE code can be read in via a single command; a plasma mesh in the Sonnet format can be read in a similar manner (Sonnet format grids are also compatible with DG). Unstructured triangular meshes can be transformed into the Sonnet format via the *tri\_to\_sonnet* routine; the input to `definegeometry2d` can then be constructed just as in the quadrilateral mesh case. When the spatial extent of the problem can be restricted to a rectangular region having no intervening material surfaces or X-points, one can use the `efit2dg2d` pre-processor to generate the more tedious parts of the `definegeometry2d` input file.

`definegeometry2d` can now handle nearly symmetric 3-D problems; the essential restriction is that all of the objects in the problem must be describable as 2-D figures swept through a range of the ignorable coordinate.

The intermediate specification of the geometry purely in terms of polygons is written out to a netCDF file. This file can be read in by the *ucd\_plot* post-processor to generate (2-D only) graphics equivalent to those produced by `geomtesta`, but at full resolution. The polygon netCDF file can also be transformed into the **Triangle** format (see below) via the *poly\_to\_tri* routine, providing an additional means of coupling to other applications.

A version of DG has been and is still included in the DEGAS 2 distribution. However, it has been used less frequently and, thus, has not been actively maintained. Users requiring additional features may want to consider the version of DG included with the SOLPS-ITER distribution (called DivGeo there); the version of Carre in that package is also much more advanced than the one in DEGAS 2. See the additional documentation in the DEGAS 2 User's Manual and in the manual provided with DG.

Note that this program makes extensive use of Jonathan Shewchuck's **Triangle** package to break polygons up into triangles. The user needs to download its source code from:

`http://www.cs.cmu.edu/~quake/triangle.html`

and arrange for the `Makefile` to find it (the default location is `$HOME/Triangle`).

## 2 Introduction and Background

This code takes a human-readable input file that, together with the other file(s) it references, describes a geometry you want to use in **DEGAS 2**. The purpose of this code is to transform that description into **DEGAS 2**'s internal description of the geometry.

The hierarchy of geometry-related objects in **DEGAS 2** is, from the lowest level to the highest level, is:

1. surface,
2. cell,
3. polygon,
4. zone.

Individual cells are composed of surfaces, as discussed in the documentation for the internal geometry (e.g., see *geometry.web*). The next level up (in two dimensions) is a polygon. This program will call various routines to break up (non-convex) polygons into cells. Finally, a zone may consist of one or more polygons; properties are constant across a zone. For example, a single zone might be used to represent the vacuum region around the plasma which is comprised of several (possibly disconnected) polygons. Or, the volume between two plasma flux surfaces in which density and temperature are constant might be a single zone. Note that polygons are used only within external interfaces such as this code. Cells and surfaces are essentially used only by the code itself; the user only deals with them in debugging. Zones are used primarily for the specification of input and output data.

The most common sources of errors in this code are associated with the violation of two basic restrictions on **DEGAS 2** geometries:

1. The problem volume (everything inside the “universal cell”) must be completely filled with user-defined zones.
2. Each surface not lying along the boundary of the universal cell must have user-defined zones on both sides of it.

If *definegeometry2d* reports an error, you have most likely violated one (or both) of these two constraints.

Another important component of the geometry are the “sectors”; they are defined at interfaces between adjacent zones of different types to facilitate tracking or between zones of the same type for diagnostic purposes. Flights are temporarily halted at sectors during tracking. If the next zone along the track represents, say, a solid material, the main code hands that flight off to the routines that effect the interaction of the current particle with that material. While stopped at that sector, scores to corresponding “diagnostics” (groups of sectors) are also tabulated. The essential identifying information of a sector are its surface and zone numbers. Currently, sectors are defined on both sides of that interface, one for each of the two adjacent zones. Both will refer to the same surface, although the surfaces will have opposite orientations.

For additional information on sectors see the documentation for the sectors class (in `src/sector.hweb` or `Doc/classes.pdf`) and the “Diagnostic Sectors” section of the User’s Manual.

This code automatically creates sectors at the interfaces between plasma / vacuum zones (i.e., zones in which flights propagate) and solid / exit zones (i.e., zones in which flights do not propagate). A sector between solid and plasma zones is defined to be a “target” sector and one between a solid and vacuum zone is a “wall” sector. The adjoining sectors are referred to as “plasma” and “vacuum” sectors, respectively. For further details, see the sector class described in *sector.hweb*.

Sectors are also labeled by a “stratum” number and a “segment” number. These labels facilitate subsequent user reference to the sectors. Since these two labels are just that, they can in principle be chosen almost arbitrarily (although the choice should be such that a given a stratum, segment pair does uniquely identify a sector). Because the process of identifying the default sectors in a problem is based on an examination of all solid and exit polygons, the stratum numbers associated with those polygons are used to label the resulting sectors *on both sides*. Consequently, stratum numbers assigned to vacuum and plasma polygons are currently not used. Default sectors defined at the edges of a *sonnet\_mesh* or *uedge\_mesh* the mesh will carry the stratum label from the adjoining solid polygon.

Each side of a polygon gives gives rise to a different surface. The sector’s “segment” number is derived from the location of that side in the polygon. Again, that segment number is used to label both sectors constructed at that interface.

The user can also specify “auxiliary sectors” that coincide with arbitrary segments of a polygon and even include segments from multiple polygons. The user can then define a diagnostic or diagnostics from either default or auxiliary sectors.

### 3 Symmetry

The `definegeometry2d` code is intended to handle 2-D and nearly symmetric 3-D planar and cylindrical geometries (for a more detailed description of geometry symmetry in DEGAS 2, see the “Symmetry and Coordinate Systems” section of the User’s Manual). In the 2-D cases, one coordinate is ignored ( $y$  in plane symmetry;  $\phi$  in cylindrical symmetry). Tracking is done in 3-D, but the zones constructed from the polygons established in `definegeometry2d` extend the full range of the ignored coordinate, providing no resolution in that direction.

In the nearly symmetric 3-D cases, the 3-D zones are again constructed by sweeping the polygons through the  $y$  or  $\phi$  coordinate. The difference is that those zones are further subdivided by  $y = \text{constant}$  or  $\phi = \text{constant}$  planes. The result is a “bread slice” (in the rectangular case) or a “pie slice” (in the cylindrical configuration) description of the geometry. Consequently, DEGAS 2 results are resolved in that direction. A second difference is that the zone type (solid, plasma, vacuum, or exit) can vary in the  $y$  or  $\phi$  direction. This capability allows some 3-D objects, such as a poloidal limiter in a tokamak, to be simulated.

## 4 How To Use This Code

Virtually all of the information in the `definegeometry2d` input file is “high level”, e.g., point coordinates rarely appear. Instead, most of the detailed information regarding points and their connectivity is contained in the other files that can, and should, be generated by other packages. The names of these files are specified in the first part of the input file. The formats that are currently in use and the corresponding keywords in the input file are (all of these are text files):

*dg\_file* An output (with extension `.dgo`) file from the DG code.

*wallfile* A simple text file containing a specified number of simply connected “walls”, with each wall consisting of a sequence of  $(X, Z)$  values.

*sonnet\_mesh* A 2-D mesh specified in the Sonnet format; e.g., as generated by the **Sonnet** or **Carre** codes.

*uedge\_mesh* A specific format used to transfer data between the **UEDGE** and **DEGAS 2** codes.

Both *dg\_file* and *wallfile* result in the definition of “walls” that can be used to construct the polygons in the second part of the `definegeometry2d` input file using the *wall* keyword. The polygons can also be constructed directly in DG using its graphical interface. These polygons are invoked in the second part of the *definegeometry2d* input file with the *dg\_polygon* keyword. A portion of the boundary of a plasma mesh imported via *sonnet\_mesh* or *uedge\_mesh* can be incorporated into a polygon via the *edge* command. A simpler approach to accomplishing the same result using DG is to associate a “mesh connection” with the polygon; an *iedge* (short for “intelligent edge”) keyword in the *definegeometry2d* input file provides the code with additional information on how to connect the mesh edge to the rest of the polygon. The corners of the universal cell (set with the *bounds* keyword) can be added to a polygon with the *outer* keyword. If points having the exact same coordinates are defined in DG, they can be used there in a *dg\_polygon* and will be recognized as being on the boundary of the universal cell.

The two most frequently used approaches to setting up a tokamak based geometry begin with files such as these generated by the **UEDGE** or **DG** codes. Typical methodologies for these two cases are:

**UEDGE** A simple geometry can be set up by using the *uedge\_mesh* keyword to establish all of the plasma zones. The *edge* and *outer* commands can be used to define solid zones that enclose this volume. Alternatively, a slightly more complicated approach involves specifying in a *wallfile* a more realistic vacuum vessel shape. The (vacuum) volume between that surface and the **UEDGE** mesh would need to be described by polygons set up using the *wall* and *edge* keywords.

**DG** The 2-D outlines of the vacuum vessel (or other hardware or surfaces) are first defined as “elements” in the DG code. These can subsequently be connected into and used to define DG’s “polygons”. Note that the Carre or Sonnet grid generation codes can be used to create Sonnet format plasma meshes that can be viewed and manipulated (in limited ways) in DG. The edges of the mesh can be incorporated into polygons with “mesh connections”. The DG elements, polygons and other information are contained in DG’s output file. Upon being read into *definegeometry2d*, these objects are reinterpreted in terms of its internal objects. The user can then utilize them in creating the polygons that will divide up the problem space.

Alternatively, there are two possible approaches to generating a new geometry from scratch:

1. If the problem possesses a basic symmetry, e.g., “plasma parameters are constant on a flux surface”, you can specify only those bounding surfaces and let *definegeometry2d* subdivide them (semi-arbitrarily) into smaller zones. First, construct a wall file containing the coordinates of each of the bounding surfaces, with each as a separate wall (see below under the *wallfile* keyword). Then, in the *definegeometry2d* input file, create a polygon out of each pair of adjacent walls, i.e., surfaces. Using the *triangulate\_to\_zones* keyword will then break these polygons up into smaller zones. The sizes of the triangles will be almost entirely controlled by the number of points used in the walls (see, however, the *triangle\_area* keyword).
2. If a mesh composed of triangles or quadrilaterals already exists, the easier approach may be to write that information in the Sonnet format. Each mesh zone in the Sonnet file format is defined by five points. These coordinates are given on three consecutive lines. The “corners” appear on the first and third lines; the second line contains the “center” point. Inside *definegeometry2d*, the four corners must trace out the shape in a clockwise fashion. While there is some freedom in the way these points are labeled, for definiteness, we will say that the first line contains the second and third points (in that order) of a quadrilateral; the third line has the first and fourth points. For a triangle, just make the two points on the third line the same (the code will also agree to call it a triangle if the third and fourth points are the same). If the center point is set exactly to zero, built in routines will be used to compute an appropriate center. As in the above example, additional data about the hardware can be specified and translated into “walls”. The mesh edges can be used together with the walls to specify the rest of the polygons required to fill the universal cell.

The DEGAS 2 User’s Manual contains two example applications of **definegeometry2d**, one demonstrating the use of DG and the other illustrating the use of an external code to create walls and polygons out of flux surfaces.

## 5 Input File

Note that the name of the input file for **definegeometry2d** is not listed in **degas2.in**. Although this might be viewed as an omission, it is consistent in that **definegeometry2d** is, in principle, one of many different means of generating **DEGAS 2** geometries and, thus, is not as fundamental as the other entries in **degas2.in**.

Instead, the command line for the execution of **definegeometry2d** specifies the name of the main **definegeometry2d** input file:

```
definegeometry2d an_input_file
```

The input file, called here **an\_input\_file**, will contain pointers to other files that provide externally generated, detailed information about the geometry. Like other text input files used in **DEGAS 2**, blank lines, spaces, and lines beginning with a comment character **#** are ignored (comments can also appear at the end of a line).

The input file consists of two sections:

1. A preparatory stage in which global parameters are set and file names are specified,
2. A “construction” section containing the specification of polygons that will fill the universal cell.

Let us introduce the components of the input file with a nontrivial example:

```
# There are two parts to the input file. The first provides global
# information.
#
# It's a good idea to set the symmetry of the problem first.

symmetry cylindrical

# The bulk of the data describing the "hardware" in this problem are
# in a file generated by the DG code.

dg_file Run35/bypass_12.dgo

# The bounds keyword specifies the size of the universal cell.

bounds 0.3 1.1 -0.8 0.7

# Another big chunk of data required in setting up the problem is the
# mesh which will store the plasma-related data. In this case, the
# mesh is provided in the Sonnet format.

sonnet_mesh Run10/cmod.carre.008 61 26

# The end_prep command terminates the first part of the input file. The
# primary task undertaken with the execution of this command is the
# generation of plasma zones from the quadrilaterals described by the
# plasma mesh.

end_prep

# In the second part of the input file, the user must define zones that
# will completely fill (without overlap) the universal cell. These
# zones are specified as the union of one or more polygons. The
# new_zone command begins the definition of the next zone; in this
# case, a solid zone. The zone definition is terminated by the next
# "new_zone" command (or an "end" or "quit"). The code will assume that
# the polygon will be closed by connecting the last point specified
# to the first point. All polygons should be convex.

new_zone solid

# The following five polygons all belong to that single zone.
# The polygons are enumerated and labeled to facilitate external reference.

# The definition of a polygon is initiated by a "new_polygon" command
# and finished by "breakup_polygon", "triangulate_polygon", or
# "triangulate_to_zones". Each of these breaks the polygon down into
# DEGAS 2's internal description consisting of cells and surfaces.
# In the last case, each of the resulting triangles is assigned a new
# zone number.
#
```

```
# Keywords like "outer", "wall", and "edge" specify single points or a
# range of points used to construct the polygon. Other keywords like
# "stratum" or "material" specify properties associated with the polygon.
# Note, however, that these properties will apply to all subsequent
# polygons until overridden by new property settings. Finally, the
# "print_polygon" command (commented out since this input file was well
# past the testing stage) writes out the points in the polygon to a
# text file so they can be analyzed or plotted externally. This is
# useful for debugging problem polygons.

end_diagnostic

# The description of this geometry in terms of polygons is written out
# to a netCDF file with this name so that it may be used again later.

polygon_nc_file Run35/bypass_12_poly_a.nc

# The "end" command instructs the code to finish setting up the
# internal geometry arrays, to check the geometry for consistency,
# and to write its netCDF file. Since the process of generating
# a geometry as complex as this one is understandably iterative, the
# code also has a "quit" command (that can be used anywhere except
# within a polygon definition) that quietly terminates the code without
# performing any of these finalization steps.

end
```

## 6 Keyword Reference

Each line in the input file is of the form: *keyword arguments* with some keywords having multiple arguments, others having none at all. Lower case single letters (perhaps with subscripts) are used to represent integer arguments. Upper case single letters correspond to real (i.e., floating point) arguments. All other arguments are strings. All keywords and strings should be lower case. This first group of keywords is intended only for use in the preparatory stage of the code; invoking them after the *end\_prep* command will likely result in the code crashing or behaving strangely.

## Preparatory Section

*symmetry* **sym** describes the symmetry of the geometry with **sym** = *plane*, *cylindrical* (“toroidal symmetry”), *oned* (for a planar system with two symmetry directions), *plane.hw* (nearly symmetric planar system with resolution in the *y* direction), *cylindrical.hw* (nearly cylindrically symmetric system with resolution in the toroidal direction), *cylindrical.section* (same as *cylindrical.hw*, but over a limited range of toroidal angles). The *symmetry* keyword must appear prior to the *end-prep* keyword.

*dg\_file* **filename** specifies the name of an output file from the DG code (with the extension **.dgo**). If **filename** does in fact contain **.dgo**, the dimensions therein are assumed to be in millimeters; filenames without this extension are assumed to have data in meters (data perhaps generated by some other means). The coordinates of the “nodes” (or points) specified in the file are read in. Their ordering in the file is that of the “elements” (or segments) to which the nodes belong. A list of elements in terms of the node numbers is compiled as the file is read in. Each of the nodes is then characterized as being of a particular type:

1. **node\_no\_elements** if the node has no corresponding elements,
2. **node\_one\_element** if the node is associated with only one element,
3. **node\_regular** if the node is associated with two elements with normals of the same sense,
4. **node\_mixed\_normals** if the node is associated with two elements having normals in opposite sense (i.e., the node is either the “start” or the “end” of both elements),
5. **node\_many\_elements** if the node represents the intersection of more than two elements.

Once each of the nodes has been characterized, the resulting information permits the translation of the elements into “walls” that can be used in the subsequent specification of polygons. The code loops over all of the irregular nodes (that are connected to at least one element). Each of these serves as the start of a wall. The rest of the wall is mapped out from the adjacent elements using the well-defined connectivity associated with the regular nodes comprising those elements. The process is stopped, of course, when the trail ends at another irregular node. A subsequent search of the elements that have not been assigned to walls is performed to identify closed surfaces consisting of only regular nodes. The upshot of this procedure is to be cognizant of the location of irregular nodes when using DG. Handling them carefully there can result in a simpler set of walls and, hence, ease the task of designing the polygons.

Suitably updated versions of DG permit the polygons to be defined there first using DG’s graphical interface. DG counts these as they are defined; the resulting integer label is used with the *dg\_polygon* keyword in the second part of the *definegeometry2d* file. In the DG output file, the polygons are delimited by a line of the form “polygon *i*”, where “*i*” is this integer label. Inside that polygon specification is the “wall” section, a list of the DG elements comprising that polygon. This is followed by a “polymat” parameter that is currently not being used; it may eventually be used to set the material associated with a polygon. Finally, the sections “meshcon1” and “meshcon2” describe connections between the elements in the polygon’s “wall” and the outer edge of the plasma mesh associated with the DG file. The code that processes the DG file assumes that these sections of the polygon specification appear in precisely this order.

*sonnet\_mesh filename n<sub>x</sub> n<sub>z</sub> i<sub>x,min</sub> i<sub>x,max</sub> i<sub>z,min</sub> i<sub>z,max</sub>* specifies a file, **filename**, containing a plasma mesh in the Sonnet format. Files not generated by Sonnet (or, equivalently, by Carre) can be used, but the user should familiarize themselves with the details of the routine that reads the file, *read\_sonnet\_mesh*. The Sonnet format specifies the plasma mesh as a  $n_x$  by  $n_z$  rectangular grid of quadrilaterals. The designation of the  $x$  and  $z$  directions is somewhat arbitrary and does not necessarily have any correspondence with the (Cartesian)  $X$  and  $Z$  coordinates referred to elsewhere in this program. The usual tokamak configuration has the  $x$  coordinate following along flux surfaces and the  $z$  coordinate going across flux surfaces. Each quadrilateral is given as a set of four corners and a center so that the mesh can be treated as completely unstructured and no connectivity information is needed. On the other hand, corners of adjacent mesh cells that are intended to match should match *exactly*. In defining the surrounding polygons, the user will undoubtedly need to be familiar with the mesh's connectivity in defining the surrounding polygons. The ordering of the corners is important. See below and in subroutine *read\_sonnet\_mesh* for more details.

If the entire mesh is to be read in, only  $n_x$  and  $n_z$  parameters need to be specified. The other four parameters allow the user to describe and use a rectangular subset of the mesh. One might want to do this if the mesh is physically much larger than the volume of interest. By isolating a subset of the mesh with these four parameters, its boundaries can be used to construct polygons via the *edge* keyword in the second part of this input file. Once the mesh subset has been read in, the original mesh indexing is forgotten. The code will proceed as if an entire mesh of size  $n_x = i_{x,max} - i_{x,min} + 1$  by  $n_z = i_{z,max} - i_{z,min} + 1$  were read in. The user will need to be mindful of this index shifting when invoking the *edge* keyword.

Note that these parameters are used as if the mesh indices begin at 1. Since the Sonnet format typically starts the mesh indices at 0, the values of  $n_x$  and  $n_z$  should be 1 greater than the indices of the last cell in the Sonnet file. The same is true for the subset indices so that, for example,  $i_{x,min} \geq 1$  and  $i_{x,max} \leq n_x$ .

*uedge\_mesh filename* specifies the name of a file, **filename**, generated by the **UEDGE** code for the purpose of transferring data to **DEGAS 2**. The file contains both geometry and plasma data, although only the former is read in by the *read\_uedge\_mesh* routine. The first few lines of the file contain additional information describing the mesh. The first line is assumed to be a comment. The first number on the second line is assumed to be  $n_x$ . Likewise, the third line provides  $n_z$ . The next three lines are ignored. As with the Sonnet format, a center and four corners are given for each quadrilateral and no connectivity information is needed. See the routine *read\_uedge\_mesh* for more details on the order of the corners.

*wallfile filename with\_sonnet* specifies the name of a file, **filename**, that contains a list of walls, each comprised by two or more points. Like other **DEGAS 2** text files, *wallfiles* can contain blank lines and comments (beginning with #). Spacing should not matter. The first line provides the number of walls in the file, *num\_new\_walls*. The following line or lines list the number of points comprising each wall. I.e., these lines must contain *num\_new\_walls* integers. The rest of the file contains the coordinates in ordered pairs, with one  $(X, Z)$  pair per line, starting with the first point of the first wall. The other points in that wall follow on consecutive lines. The points in the second wall (if there is one) come after that. Comments can be inserted between walls to facilitate legibility. For simple one wall systems, the file can be easily created by hand. For more complicated systems involving several walls, the user may benefit from writing a code to generate the file.

The optional argument **with\_sonnet** should be used if the coordinates in the *wallfile* are supposed to coincide with coordinates in a Sonnet format mesh. Since the latter are restricted to 10 digits of precision, a similar truncation is applied to the *wallfile* coordinates in this case.

*print\_min\_max* loops over all of the nodes (read in via the *dg\_file* or *wallfile* keywords) and prints to standard out the maximum and minimum  $R$  and  $Z$  values (in meters). These can be useful in choosing suitable bounds for the universal cell.

*bounds*  $X_{\min} X_{\max} Z_{\min} Z_{\max} Y_{\min} Y_{\max}$  specifies the corners of the universal cell in  $X$  ( $X_{\min} \rightarrow X_{\max}$ ),  $Z$  ( $Z_{\min} \rightarrow Z_{\max}$ ), and in nearly symmetric 3-D cases  $Y$  or  $\phi$  ( $Y_{\min} \rightarrow Y_{\max}$ ). The *outer* keyword can be used to incorporate these points into polygons.

The  $Y$  values are not needed for 2-D (*symmetry = plane* or *cylindrical*) or full torus 3-D (*symmetry = cylindrical.hw*) cases. For nearly symmetric 3-D plane cases (*symmetry = plane.hw*), the  $Y$  values are in meters. For 3-D cylindrical section cases (*symmetry = cylindrical.section*), the  $Y$  values describe the range of toroidal angles in degrees that are to be used in the problem (note, however, that these are converted to radians during processing). Negative values are permitted, e.g., so that the user can put  $\phi = 0$  in a convenient location. The only constraint is that  $0 < Y_{\max} - Y_{\min} < 360^\circ$ . When the universal cell is defined with the invocation of the *end\_prep* command, it will have surfaces at  $\phi = Y_{\min}$  and  $\phi = Y_{\max}$ . for the full torus 3-D (*cylindrical.hw*) case,  $Y_{\min}$  and  $Y_{\max}$  may be specified; if they are not, they are assumed to be  $Y_{\min} = 0$  and  $Y_{\max} = 360^\circ$ .

*print\_walls* **format filename** instructs the code to write out the current set of walls. If **filename** is not provided, the data are written to standard out. There are two possible **formats**. The first, **tabular**, has the walls laid out in successive columns, suitable for plotting with an external program. The second, **linear**) is consistent with the format used by the *wallfile* keyword.

*uniform\_ys*  $n_y$  sets up a uniform grid in the  $y$  or  $\phi$  direction of nearly symmetric 3-D problems. This keyword can only be used with *symmetry* values *plane.hw*, *cylindrical.hw*, and *cylindrical.section*. In all three cases,  $n_y$  uniformly spaced  $y = \text{constant}$  or  $\phi = \text{constant}$  surfaces will be defined, breaking the problem up into equal size  $n_y - 1$  zones in the third dimension.

In the *plane.hw* and *cylindrical.section* cases, the first and last of these surfaces are offset from the universal cell surfaces at  $Y_{\min}$  and  $Y_{\max}$  by a small amount,  $0.01(Y_{\max} - Y_{\min})$ , so that border zones can be defined there.

*y\_values* **filename OR**  $y_1 y_2 y_3 \dots$  This keyword allows the user to directly specify the grid in the  $y$  or  $\phi$  direction for nearly symmetric 3-D problems. This keyword can only be used with *symmetry* values *plane.hw*, *cylindrical.hw*, and *cylindrical.section*. In planar cases, the  $y_i$  values are in meters; in cylindrical cases, they are in degrees (but converted to radians internally). In all instances, the user must have  $Y_{\min} \leq y_i \leq Y_{\max}$  with the  $y_i$  monotonically increasing with  $0 \leq i \leq n_y - 1$  (there will be  $n_y$  surfaces defined at the specified  $y$  values; hence, there are  $n_y - 1$  segments in the third dimension). In the bounded cases (i.e., not *cylindrical.hw*), a small gap is needed between the first and last surfaces and the bounding universal cell surfaces,  $y_0 > Y_{\min}$  and  $y_{n_y-1} < Y_{\max}$ . In full toroidal cases (*cylindrical.hw*), the code expects  $y_0 = Y_{\min}$  and  $y_{n_y-1} = Y_{\max}$ . If the list of  $y$  values is too long to fit on a single line, they can instead be put into a file **filename**, one per line. This also facilitates commenting as in other DEGAS 2 text input files. Note that this keyword should appear after *symmetry* and *bounds* since the corresponding input information is used in checking the *y\_values*.

*end\_prep* terminates the preparatory stage of the code. Dynamically allocated arrays associated with nodes, elements, and walls are trimmed to their final sizes, and the universal cell is established. If a plasma mesh has been specified via the *sonnet.mesh* or *uedge.mesh* keywords, the constituent quadrilaterals are translated into polygons and then decomposed into the internal elements of the DEGAS 2 geometry with each quadrilateral corresponding to a plasma zone. One advantage of making these the first zones defined in the problem is that transfer of zone-based output information to other codes (such as a fluid plasma code) is simplified.

**Construction Section** The rest of the keywords are associated with the “construction” section of the input file. While they may (even legally) be used prior to the *end\_prep* command, such usage is not encouraged in the interest of maintaining the simplicity of the input file. One exception is the *quit* keyword that can be used anywhere in the input file (except inside a polygon definition). There is a further subdivision in that all keywords regarding a specific polygon must appear between its *new\_polygon* command and the command that denotes its completion (*clear\_polygon*, *breakup\_polygon*, *triangulate\_polygon*, or *triangulate\_to\_zones*). Likewise, all of the keywords pertaining to a diagnostic must appear between its *new\_diagnostic* and *end\_diagnostic* commands.

*new\_zone type alt\_type i<sub>1</sub> i<sub>2</sub> i<sub>3</sub> ...* starts definition of a new zone. All polygons specified after this command and prior to the next *new\_zone* command will be added to this zone. For 2-D problems, just the first argument, **type**, is allowed. The possible values of **type** are **vacuum**, **plasma**, **solid**, and **exit**.

In nearly symmetric 3-D cases (*symmetry* must be *plane\_hw*, *cylindrical\_hw* or *cylindrical\_section*), the zone type can be varied in the third dimension. If no variation is desired, again specify just the **type** with the *new\_zone* command. To use mixed zone types, use the first argument **type** to specify the dominant zone type. The second zone type and its locations are determined by the remaining arguments. The **alt\_type** provides the zone type and again must be **vacuum**, **plasma**, or **solid**. The following indices correspond to the grid in the *y* or  $\phi$  locations specified by the *uniform\_ys* or *y\_values* keyword. The first segment of the grid corresponds to  $i = 0$ ; the last to  $i = n_y - 2$  (since there are  $n_y - 1$  segments in the third dimension).

For convenience, a range of *i* values can be specified as *i - j* (with a space on either side of “-”). That is, the range “3 4 5 6” could be abbreviated as “3 - 6”.

Zones of mixed type must be decomposed with the *triangulate\_to\_zones* command. Note that currently this option cannot be used with exit zones. Nearly the same functionality can be obtained by specifying a solid zone with a recycling coefficient of zero.

*new\_polygon* begins the definition of a new polygon. The following keywords (down to and including *triangulate\_to\_zones*) can be used in describing this polygon.

*outer i j k* adds to the current polygon the *i*th, *j*th, and *k*th points of the bounding rectangle of the problem (defined with the *bounds* keyword, i.e., the minimum and maximum *X* and *Z* used to define DEGAS 2’s “universal cell”). The numbering of the corners is clockwise:

- 0 (or 4) ( $X_{\min}, Z_{\min}$ )
- 1        ( $X_{\min}, Z_{\max}$ )
- 2        ( $X_{\max}, Z_{\max}$ )
- 3        ( $X_{\max}, Z_{\min}$ )

There can be any number of arguments (e.g., see the above example input file).

*wall i<sub>wall</sub> j<sub>start</sub> j<sub>stop</sub> reverse* takes points from wall number *i<sub>wall</sub>* that was specified with either the *wallfile* or *dg\_file* command. The parameters *j<sub>start</sub>* and *j<sub>stop</sub>* prescribe which points from that wall to use. Note that the first point of the wall is numbered 0 so that the only valid values of *j<sub>start</sub>* and *j<sub>stop</sub>* are between 0 and the number of elements in the wall. If the wall needs to be traversed in the reverse direction, *j<sub>stop</sub>* can be set less than *j<sub>start</sub>*. If *j<sub>start</sub>* = *j<sub>stop</sub>*, a single point is added to the polygon. If both *j<sub>start</sub>* and *j<sub>stop</sub>* are replaced by a single \*, all of the points in the wall are used. The wildcard character can also be used as: *j<sub>start</sub> \** to indicate that all of the points from *j<sub>start</sub>* to the end of the wall should be used. The additional argument **reverse** can be added at the end of the line to reverse the ordering of the points indicated by *j<sub>start</sub>*, *j<sub>stop</sub>*, and / or \*. The primary usage of **reverse**, however, will be in conjunction with \*.

*edge*  $i_{x,start}$   $i_{x,stop}$   $i_{z,start}$   $i_{z,stop}$  **xcut** **reverse** takes an “edge” from a plasma mesh defined with either the *sonnet\_mesh* or *uedge\_mesh* keywords and adds it to the current polygon. To properly refer to an edge, the arguments must be such that either  $i_{x,start} = i_{x,stop}$  or  $i_{z,start} = i_{z,stop}$ . Valid values of  $i_{x,start}$  and  $i_{x,stop}$  will be between 0 and  $n_x$ , inclusive. Likewise,  $i_{z,start}$  and  $i_{z,stop}$  will be between 0 and  $n_z$ . Either pair can be replaced with  $*$  to indicate that the entire edge should be added to the polygon. The code used to process the arguments “knows” about the four corners comprising each mesh zone so that **edge**  $* 0 0$  actually refers  $n_x + 1$  points (see also the additional detail below on corners). If a subset of a Sonnet mesh is being used, these values are relative to it, not to the original, full mesh.

The one instance where this is not quite true is at a discontinuity (a “cut”) in the  $x$  direction of the computational mesh. On the “right” side of the cut (“right” in the topological sense; i.e., the mesh cells  $i_x$  and  $i_x - 1$  do *not* share a common edge), adding the optional *xcut* argument to the *edge* command with  $i_{x,start} = i_{x,stop} = i_x$  will allow the edge of the  $i_x$  cell along this cut to be added to the polygon. Without the *xcut* argument, this command would instead yield segments following the boundary between the  $i_x$  and  $i_x + 1$  cells. On the “left” side of the cut (the mesh cells  $i_x$  and  $i_x + 1$  do not share a common edge), the usual *edge* command with  $i_{x,start} = i_{x,stop} = i_x$  will work as is, and the *xcut* command is not needed. The *xcut* argument may also be needed in conjunction with an  $i_{y,start} = i_{y,stop}$  edge to specify a single point on the “right” side of a cut. Doing so requires a *separate edge* command for that point (i.e., it would have both  $i_{x,start} = i_{x,stop}$  and  $i_{y,start} = i_{y,stop}$ , as well as the *xcut* argument). The specific implementation of the *xcut* option is described below under “Other Considerations”.

As with the *wall* keyword, the *reverse* argument can be used to indicate that the points should be added to the polygon in the order opposite to that indicated by the other arguments. One, none, or both of the *xcut* and *reverse* options may appear. If both are present, they do not need to be in a particular order.

*dg-polygon*  $i_{\text{polygon}}$  adds the segments associated with the  $i_{\text{polygon}}$ th polygon defined in DG to the current polygon. This functionality allows the user to set up polygons in DG rather than going through the more tedious and error prone process of defining them in this input file with the *wall* and *outer* keywords. Different types of DG polygons are possible:

1. If the DG polygon defines a closed figure, no other points need be specified for this *new-polygon* group, although the user should still assign *stratum*, *material*, *temperature*, and *recyc-coef* values as needed. The resulting polygon will have a clockwise orientation.
2. If the polygon is not closed, it can be closed by various means,
  - (a) The DG polygon’s “mesh connection” data identify a single point on the edge of the plasma mesh. This point will be used to close the polygon without any additional input from the user.
  - (b) The DG polygon’s “mesh connection” data identify a pair of points on edge of the plasma mesh, with the implication that the set of mesh edge elements “between” them will be used to close the polygon. However, this set is uncertain since it could consist of either the clockwise or counter-clockwise path between the specified points; the user must invoke an *iedge* command to determine which should be used.
  - (c) No “mesh connection” data are specified. This would be the case if the user wishes to complete the polygon with another command (e.g., *edge* or *wall*); *dg-polygon* must be the first command to add points to the polygon in this case. This approach is not recommended since the orientation of the DG polygon may not be as expected. If that is the case, the user can invoke the *reverse* command immediately after *dg-polygon*.

*iedge* **edge**<sub>1</sub> . . . specifies one or more edges of plasma mesh defined with either the *sonnet\_mesh* or *uedge\_mesh* keywords. The edges are identified by the strings *S*, *E*, *N*, and *W* (referring to south, east, north, and west), corresponding to the  $i_z = 0$ ,  $i_x = n_x$ ,  $i_z = n_z$ ,  $i_x = 0$  boundaries, respectively.

*reverse* instructs the code to reverse the order of all points that have been added to the current polygon; the polygon need not be complete.

*stratum*  $i_{\text{stratum}}$  labels the polygon as belonging to stratum number  $i_{\text{stratum}}$ . It will be applied to subsequent polygons until used again.

*material* **mat** sets the material for the polygon to the material having the symbol **mat**. A material with this symbol must appear in the *materials\_infile* (named in the *degas2.in* file) for this run. It will be applied to all subsequent polygons until used again. Note that this setting only affects the calculation when one or more edges of this polygon ends up being a target or wall sector.

*temperature*  $T$  associates a temperature of  $T$  Kelvin (a real number) to the polygon. Its value currently is used only to determine the energy of desorbed species, although other applications may be incorporated. It will be applied to all subsequent polygons until used again. Note that this setting only affects the calculation when one or more edges of this polygon ends up being a target or wall sector.

*recyc\_coef*  $R$  associates a recycling coefficient of  $R$  ( $R$  a real number,  $0 \leq R \leq 1$ ) to the polygon. It will be applied to all subsequent polygons until used again. Note that this setting only affects the calculation when one or more edges of this polygon ends up being a target or wall sector. Setting  $R = 0$  allows a purely absorbing boundary to be modeled.

*triangle\_area*  $A$  specifies a minimum area in square meters for the triangles to be created by **Triangle** (with  $A$  a real number) when the *triangulate\_to\_zones* command is executed. Practically, it seems that this ends up as little more than a suggestion. The reason is that we cannot allow **Triangle** to add points along the boundary of the polygon. Although this would not compromise the definition of **DEGAS 2** surfaces from the triangulation of the current polygon, the surface(s) of the adjacent polygon(s) would not be subdivided in the same way. Hence, the exact correspondence of adjacent surfaces that the code relies upon for establishing connectivity would be destroyed. **Triangle** can, however, add points to the interior of a polygon; this parameter  $A$  can be used to control that process.

*triangle\_hole*  $n$   $X$   $Z$  specifies an integer number of holes,  $n$ . This is currently constrained to be a single hole,  $n = 1$ . The coordinates (real numbers) of the hole are given as  $X$  and  $Z$ . The hole location is used by **Triangle** when either the *triangulate\_polygon* or *triangulate\_to\_zones* command is executed on a polygon that encircles a region that is *not* to be broken up into triangles. The hole location can be anywhere in this interior region.

*aux\_stratum*  $i_{\text{stratum}}$  initiates the definition of an auxiliary stratum (consisting of one or more auxiliary sectors) labeled as stratum number  $i_{\text{stratum}}$ . The definition is terminated by an *end\_aux\_stratum* command. All of the polygon segments specified between the two commands will be used to define auxiliary sectors in this stratum. More precisely, sectors will be set up starting at each *point* between the two commands; the end point of each sector being the next point in the polygon. Thus, the end point of the last auxiliary sector is the first point specified *after* the *end\_aux\_stratum* command. For this to work correctly, *the polygon must have a clockwise orientation*. The *aux\_stratum* and *end\_aux\_stratum* commands may be invoked multiple times across various polygons, with the same or different values of  $i_{\text{stratum}}$ . In this way, segments of multiple polygons can be incorporated into a single stratum.

*end\_aux\_stratum* terminates the definition of an auxiliary stratum begun with an *aux\_stratum* command.

*print\_polygon* **filename** prints the points of the current polygon to a file, **filename**. If **filename** is not present, the coordinates are written to standard out.

*clear\_polygon* will cause the code to completely forget about this polygon in subsequent operations. This is useful for checking the integrity of several polygons with a single run of the code.

*breakup\_polygon* instructs the code to use DEGAS 2's original *decompose\_polygon* routine to break the polygon up into the internal geometry elements. This routine expects the polygon to be traced out in a clockwise direction. Note also that *decompose\_polygon* is far from foolproof and will occasionally fail with a "unable to decompose polygon" error. This problem can usually be remedied by choosing a different point of the polygon as the first point. On the other hand, the functionality of the vastly more robust *triangulate\_polygon* routine is equivalent. So, try using it instead when this error arises. The two approaches may result in different run efficiencies, but no such variability has ever been established.

*triangulate\_polygon* instructs the code to use the **Triangle** package to break the polygon up into DEGAS 2's internal geometry elements. The **Triangle** routine is extremely tolerant and robust; the input polygon can be traced out in either direction. However, a clockwise orientation is recommended since this will preserve (as *strata\_segment* labels) the relationship between the resulting bounding segments and the original polygon points. This command does only a basic triangulation and is only recommended for use with polygons in solid zones. In nearly symmetric 3-D cases, these zones *will not* be resolved in the  $i_y$  direction.

*triangulate\_to\_zones* instructs the code to use the **Triangle** package to break the polygon up into DEGAS 2's internal geometry elements. The **Triangle** routine is extremely tolerant and robust; the input polygon can be traced out in either direction. Each resulting triangle is added to the geometry as a separate zone (of the current type). A second refining call to **Triangle** beyond the one analogous to that done with *triangulate\_polygon* is performed that permits the application of additional constraints such as a minimum area. A clockwise orientation is recommended since this will preserve (as *strata\_segment* labels) the relationship between the resulting bounding segments and the original polygon points. This option also ensures that zones are resolved in the  $i_y$  direction in nearly symmetric 3-D problems. **Note: the next polygon to appear in the file must be preceded by a *new\_zone* command.** (This is the last of the polygon-specific keywords.)

*new\_diagnostic* **diagnostic name** initiates the definition of a diagnostic group (of sectors) associated with the name **diagnostic name** (the name of the diagnostic may contain spaces). **The following keywords can be used to describe this diagnostic.** An *end\_diagnostic* command terminates its definition. The only other command that must be used is *stratum*; the others listed below are optional.

*stratum*  $i_{\text{stratum}}$  **type** designates a previously defined stratum that will determine the sectors to be used for this diagnostic. If  $i_{\text{stratum}}$  is associated with a default sector (i.e., corresponds to a stratum number specified with the *stratum* keyword inside a polygon or diagnostic definition), the optional argument **type** determines which of the two types of default sectors will be used. If **type** is set to **solid**, the diagnostic will be comprised of the wall, target, or exit sectors created from that polygon with that stratum label. If the **type** argument is omitted, its value is assumed to be **solid**. Alternatively, if **type** is set to **nonsolid**, the adjoining plasma or vacuum sectors are used. When an auxiliary stratum is used, all sectors of that stratum will be incorporated.

This capability can be used to duplicate and / or extend (e.g., to increase resolution in energy or angle of incidence) the default diagnostics and associated tallies without having to modify the code.

*variable* **var** requests that an independent variable mesh for the physical quantity **var** be set up for the diagnostic being defined by a preceding *new\_diagnostic* command. The default is no variable; in that case, the diagnostic lumps together all flights passing through its sectors. By using **energy** or **angle** for **var**, the user can resolve these passages according to the flights energy or angle (angle of incidence relative to the normal to the sector), respectively. The user can control the units used for the energy mesh by instead using for **var** **energy J** or **energy eV** (the default is eV). Likewise, the angle can be in degrees, **angle degrees** (default) or radians, **angle radians**.

**number**  $n_{\text{var}}$  specifies the number of values in the independent variable mesh for the diagnostic being defined in conjunction with a preceding *new\_diagnostic* command.

*minimum*  $V_{\min}$  specifies the minimum value of an independent variable mesh being defined in conjunction with a preceding *new\_diagnostic* command.

*maximum*  $V_{\max}$  specifies the maximum value of an independent variable mesh being defined in conjunction with a preceding *new\_diagnostic* command.

*multiplier*  $F$  specifies a multiplier to be applied to the *maximum* and *minimum* of a diagnostic independent variable mesh. This command allows the user to utilize units *other than* those described above under *variable*. The multiplier must result in MKS units for the mesh (i.e., J for energy and radians for angle).

*spacing* **spac** specifies the spacing of an independent variable mesh being defined by a preceding *new\_diagnostic* command. The only valid values for **spac** are **linear** and **log**. No default is set, so one of these must appear explicitly.

*end\_diagnostic* terminates the definition of the diagnostic begun with a preceding *new\_diagnostic* command.

*y\_min\_zone* **mat**  $i_{\text{stratum}}$   $i_{p,\text{stratum}}$  specifies that the  $Y_{\min}$  boundary of bounded, nearly symmetric 3-D cases (*symmetry* = *plane.hw* or *cylindrical\_section*) is to be assigned the material with symbol **mat**. A material with this symbol must appear in the *materials\_infile* (named in the *degas2.in* file). Sectors based on this zone will be labeled with stratum number  $i_{\text{stratum}}$ . If the optional second stratum label  $i_{p,\text{stratum}}$  is present, sectors based on the adjacent (corresponding to  $i_y = 0$ ) zone are also defined and assigned stratum label  $i_{p,\text{stratum}}$ .

*y\_max\_zone* **mat**  $i_{\text{stratum}}$   $i_{p,\text{stratum}}$  specifies that the  $Y_{\max}$  boundary of bounded, nearly symmetric 3-D cases (*symmetry* = *plane.hw* or *cylindrical\_section*) is to be assigned the material with symbol **mat**. A material with this symbol must appear in the *materials\_infile* (named in the *degas2.in* file). Sectors based on this zone will be labeled with stratum number  $i_{\text{stratum}}$ . If the optional second stratum label  $i_{p,\text{stratum}}$  is present, sectors based on the adjacent (corresponding to  $i_y = n_y - 2$ ) zone are also defined and assigned stratum label  $i_{p,\text{stratum}}$ .

*polygon\_nc\_file* **filename** will cause the netCDF file containing the polygon description of the geometry (based on the **g2** class, as described in the file *geometry2d.hweb*) to be named **filename**. The default file name is **polygon.nc**.

*quit* causes the code to terminate immediately. This is useful for preliminary runs in which the geometry is known to be inconsistent or incomplete, but the code needs to be run so that walls or polygons can be printed out for external examination.

**end** denotes completion of the geometry specification. A variety of derived relationships are set up by subroutine calls. The geometry is checked (thoroughly) and written to its netCDF file.

## 7 Other Considerations

*Regarding corners with the edge keyword:* Because the **UEDGE** and **Sonnet** mesh formats both provide four corners for each mesh zone, the number of points along each “edge” of the mesh is one greater than the number of zones along that edge. This fact must be taken into account in defining polygons along these edges.

For clarity, here is the convention used to number the corners in *definegeometry2d*:

In the **Sonnet** mesh format, the first line contains corners 2 and 3. The second line specifies the center. Corners 1 and 4 are on the third line. The **UEDGE** mesh format specifies the corners for each point in the order 0 (center), 1, 4, 2, and 3.

For a particular  $(i_x, i_z)$  specified via arguments to the *edge* keyword, the logic that determines the corner to be used is:

1. If  $i_x = 0$  and  $i_z = 0$ , corner 1 of the  $(1, 1)$  zone (recall that there is no  $(0, 0)$  zone).
2. If  $i_x = 0$ , but  $i_z \neq 0$ , corner 2 of the  $(1, i_z)$  zone.
3. If  $i_x \neq 0$ , but  $i_z = 0$ , corner 4 of the  $(i_x, 1)$  zone.
4. Otherwise, use corner 3 of the  $(i_x, i_z)$  zone.

If the *xcut* argument for the *edge* keyword has been invoked, a separate set of logic is required:

1.  $i_x \neq 0$  is asserted. The above logic already handles this case.
2. If  $i_z = 0$ , corner 1 of the  $(i_x, 1)$  zone.
3. Otherwise, use corner 2 of the  $(i_x, i_z)$  zone.

In this way, the “left” edge of the  $i_x$  zone can be specified; the usual logic results in the “right” edge (except at  $i_x = 0$ ).

*Regarding the definition of detectors:* Ideally the user would also be able to specify detectors via this input file. Instead, a placeholder subroutine called *detector\_setup* has been defined in the file *def2ddetector.web*. The user can write a replacement routine that will be loaded in automatically if it is in a file named *usr2ddetector.web*. An example is contained in the file *btopdetector.web*. In practice, one would use such a file by executing commands analogous to:

```
cd $HOME/degas2/src
cp btopdetector.web usr2ddetector.web
touch usr2ddetector.web
cd ../SUN
gmake definegeometry2d
```

Likewise, to revert to the default (null) subroutine,

```
cd $HOME/degas2/src
rm usr2ddetector.web
touch def2ddetector.web
cd ../SUN
gmake definegeometry2d
```

Note the use of the **touch** command to make sure **gmake** recognizes the change.

*Regarding the orientation of sectors:* Sectors are defined using a zone and a surface bounding that zone. A flight leaving that zone through that surface is considered to be traveling “out” of that sector, establishing the applicability of the direction-sensitive variables available in **tallysetup**. For example, the flight would make a contribution to a sector-based tally for which the dependent variable is **mass\_out**, but not for one in which the variable is **mass\_in**.

The default diagnostics (see the “Diagnostic Sectors” section of the User’s Manual) are comprised of default wall, target, and exit sectors. So, flights traveling out of adjacent plasma or vacuum zones “into” a sector incorporated into one of these diagnostic groups will make contributions to corresponding tallies that have a dependent variable of **mass\_in**, **momentum\_in\_vector**, or **energy\_in**; these tallies represent sinks for the test species.

If the plasma-material interaction processes that result from the flight striking this surface yield one or more products to be tracked back into the plasma or vacuum, contributions will be made to tallies based on the same diagnostic group but having an outwardly directed dependent variable (e.g., **mass\_out**).

The “auxiliary sectors” capability provided by this code allows the definition of:

1. Wall, target, or exit sectors at locations of specific interest. Such sectors will work just as the corresponding default sectors do.
2. Vacuum or plasma sectors at locations of specific interest. In nearly symmetric 3-D cases, these might be used to determine the variation of fluxes in the third dimension. These can also be used to track fluxes between adjoining plasma or vacuum zones, where there are no default sectors at all.

The former are set up using the *aux-stratum* and *end-aux-stratum* commands inside a solid polygon definition clause. The latter would have these keywords inside a vacuum or plasma polygon definition. The direction-sensitive variables for the former behave as above; the latter work in the opposing manner. I.e., a **mass\_in** based tally represents a source for a plasma or vacuum sector. Since nothing should be lost across the interface, the “**mass\_in**” contribution to a solid sector should equal the **mass\_out** of an adjoining plasma or vacuum sector (of the same extent in the third dimension), and vice versa.

*Special note on comments and debuggers:* Part of this file is written in C. The current Sun Workshop debugger (there may be others) utilizes the original FWEB file in stepping through the source code of the C routines. Getting the object file and the source code lines to match up requires exercising some care in writing comments. First, do not use the `//` comment style on a single line. Second, do not put blank lines before or after multiline (delimited by `/*    */`) comments. There may be other requirements as well.

## 11 Read wall file

This is intended to duplicate the wallfile functionality provided in *readgeometry*. At the same time, this format should allow a file generated with the “linear” format of this code’s *print\_walls* keyword to be read back in. Hence, the numbers on the second line of the file represent the **number of points, not the number of segments**, as was the case in *readgeometry*. The points listed are checked against the existing list of nodes. If new, they are added. Either way, the new walls are stored as a list of nodes, just as are those generated from a DG file. Note that we presently make no attempt to update the elements. Only the node numbers and coordinates are used later in the code.

⟨ Read Wall File 11 ⟩ ≡

    direction in order to preserve segment number. First, assume that the user does
    likewise in specifying auxiliary strata. Then, the selected polygon segment consists
    of the point indicated by temp_stratum_ptsk and that point number plus one. The
    corresponding triangle side must be labeled with both of these point numbers.
    Again, because we know the triangles are all clockwise, we can assume that the i + 1
    segment would match the larger point number. Furthermore, since the i = 0 and
    i = 3 points are the same, we don't have to worry that i = 3 will be hit first. One
    thing missed on first implementation was the need for the mod function here when
    the desired segment is the last one in the original polygon so that the second point in
    the segment has been assigned 0 instead of n. Also, initial code just had the assert
    below on i, allowing temp_segmentj,4 to be evaluated, accessing undefined memory.
    Instead, we now exclude i = 3 from the above if-then clause. */

## 20 Print wall coordinates to a file for user examination

There are two possible formats. The first (“tabular”) has the walls laid out in successive columns, suitable for plotting with an external program. The second (“linear”) is consistent with the format used by the “wallfile” keyword. The user can provide the name of the file. If absent, the data are written to stdout.

```
"definegeometry2d.f" 20 ≡

## 21 Read input lines specifying a polygon

The structures in the argument list can get a little confusing. Let's spell them out here at least.

*nunit* The logical unit number to which the input file is attached.

*num\_walls* Number of walls created during the preparatory stage, either from a *wallfile* or a *dg\_file* command.

*wall\_segment\_count* Number of elements (or, equivalently, segments) in each of these walls.

*wall\_nodes* List of nodes comprising these walls. Because the wall nodes and elements are constructed together at the same time, they are trivially related and only the nodes are needed here. This array just contains pointers into the *nodes* array.

*nodes* Coordinates of all of the nodes specified in the preparatory stage via the *wallfile* and *dg\_file* commands.

*dg\_elements\_list* List of the “start” and “end” nodes associated with each element described in the *dg\_file*.

*num\_dg\_poly* Number of “polygons” (in the DG sense) contained in the *dg\_file*. Note that these may be open or closed.

*dg\_poly\_num\_elements* Number of elements in each of the DG polygons contained in the *dg\_file*.

*dg\_polygons* List of elements in each of the DG polygons contained in the *dg\_file*.

*dg\_poly\_num\_meshcon* Number of mesh connections (referred to as “meshcon”) associated with each DG polygon. Currently, the only valid values are 0, 1, or 2.

*dg\_poly\_meshcon* Integer label partially identifying the mesh connections associated with each DG polygon.

*dg\_poly\_meshcon\_hv* Switch (= *mesh\_h*  $\leftrightarrow$  “horizontal” or *mesh\_v*  $\leftrightarrow$  “vertical”) completing the identification of the mesh connections associated with each DG polygon.

*xb\_min* Minimum value of  $x$  as set with the *bounds* command.

*xb\_max* Maximum value of  $x$  as set with the *bounds* command.

*zb\_min* Minimum value of  $z$  as set with the *bounds* command.

*zb\_max* Maximum value of  $z$  as set with the *bounds* command.

*nxd* Number of cells in the first dimension of the input Sonnet or UEDGE mesh.

*nzd* Number of cells in the second dimension of the input Sonnet or UEDGE mesh.

*mesh\_xz* Coordinates of the input Sonnet or UEDGE mesh.

*mesh\_nodes* A list of (unique) nodes created from the four edges of the input Sonnet or UEDGE mesh. This array contains the coordinates rather than pointers to another array. These nodes are independent of those mentioned above.

*mesh\_elements* Full list of the “start” and “end” nodes associated with each element created from the four edges of the input Sonnet or UEDGE mesh. No assumptions are made regarding the order or connectivity of the entries in this list.

*mesh\_edge\_num\_elements* Number of elements (or segments) on each of the four edges of the input Sonnet or UEDGE mesh.

*mesh\_edge\_elements* List of (with *mesh\_edge\_num\_elements* telling how many) elements in each of the four edges of the input Sonnet or UEDGE mesh.

*mesh\_edge\_dg\_label* Integer used by DG to partially label mesh elements.

*mesh\_edge\_hv* Switch (= *mesh\_h*  $\leftrightarrow$  “horizontal” or *mesh\_v*  $\leftrightarrow$  “vertical”) that completes DG’s label for the mesh elements.

*mesh\_curve\_num* Array dimensioned in the calling program for use below by the *iedge* command. It will contain labels identifying which of one or more simply connected “curves” (equivalent to “walls”) created from the mesh edges.

*mesh\_scratch* Array dimensioned in the calling program to provide scratch space for the *iedge* command.

*vc\_cross*(*b\_vec*, *c\_vec*, *bc\_cross*)

*area* = *half* \* *vc\_abs*(*bc\_cross*)    /\* Use  $\alpha$ ,  $\beta$ ,  $\gamma$  to denote the trilinear coordinate values. A constant of proportionality  $k$  relates these to the distances of the points to the triangle sides.  $k$  can be determined for any particular set of coordinates via the area of the triangle.

$$k \equiv \frac{2\Delta}{a\alpha + b\beta + c\gamma},$$

In the case of the centroid with  $\alpha = 1/a$ , etc., the denominator is just 3. \*/

*alpha* = *one* / *a*

*gamma* = *one* / *c*

*k* = *two* \* *area* / *const*(3.)    /\* The vectors used in the Web page referred to in the introduction to this routine do not appear to be a consistent set. The vectors we use here along the sides trace out the triangle in a clockwise direction. The Cartesian coordinates of the point of interest are written in terms of some distance  $l_c$  along side  $c$  (starting at vertex A) plus a distance  $k\gamma$  along  $\hat{c}_\perp$  (by definition of  $\gamma$ ). A similar expression is written going from vertex C along  $-\hat{a}$ , and the two are solved for the two distances along the sides. We only need one here:

$$l_c = \frac{-k\alpha + \gamma k(\hat{a}_1\hat{c}_1 + \hat{a}_3\hat{c}_3) + \hat{a}_3(A_1 - C_1) + \hat{a}_1(C_3 - A_3)}{\hat{a}_1\hat{c}_3 - \hat{a}_3\hat{c}_1}.$$

**Note:**  $l_c$  can be negative for a really stretched out triangle. \*/

*den* = *a\_hat*<sub>1</sub> \* *c\_hat*<sub>3</sub> - *a\_hat*<sub>3</sub> \* *c\_hat*<sub>1</sub>

*assert*(*den* > *zero*)

## 26    Compute the center of a quadrilateral

```

⟨Functions and subroutines 8⟩ +≡
  subroutine quad_center(quad, center)

    implicit_none_f77
    implicit_none_f90

    real quad0:4,g2_x:g2_z     // Input
    vc_decl(center)
    // Output /* Use this as a temporary approximation. To be useful, zone must be convex.
    vc_set(center, const(0.25) * (quad0,g2_x + quad1,g2_x + quad2,g2_x + quad3,g2_x), zero,
    const(0.25) * (quad0,g2_z + quad1,g2_z + quad2,g2_z + quad3,g2_z))

    return
end

```

## 27    Compute area of a closed polygon

This routine computes the area of a plane polygon using the formula employed in *polygon\_volume*. That routine deals with the more general problem of computing the volume in both rectilinear and cylindrical geometries. The intended application of this more basic routine is to determine whether the points of a polygon are ordered clockwise (positive result) or counterclockwise (negative). As such, a simpler, self-contained routine is suitable.

There are  $n + 1$  points in the polygon. The numbering starts at 0 and ends at  $n$ . The coincidence of those two points is checked. This formula requires few other assumptions. Duplicate points can appear. Segments may be colinear. “Holes” can even be accounted for as long as they are specified as part of a single list of connected points. I.e., this is the same manner used for specifying for Triangle polygons with holes.

```

⟨Functions and subroutines 8⟩ +≡
  function polygon_area(n, x)
    implicit_none_f77
    implicit_none_f90
    real polygon_area     // Function
    integer n     // Input
    real x0:n,g2_x:g2_z
    integer i     // Local
    real area     /* Use a local variable to facilitate debugging. */

    assert(x0,g2_x ≡ xn,g2_x)
    assert(x0,g2_z ≡ xn,g2_z)
    area = zero
    do i = 0, n - 1
      area += half * (xi,g2_x + xi+1,g2_x) * (xi,g2_z - xi+1,g2_z)
    end do

    polygon_area = area

    return
end

```

## 28    Reverse order of polygon points

The objective of this routine is to transform a counter-clockwise oriented polygon into one with clockwise orientation. While those designations make sense only for closed polygons, the routine will, of course, work on an arbitrary list of points. The input integer  $n$  gives the number of sides of the polygon; there are  $n + 1$  points, numbered 0 through  $n$ .

⟨ Functions and subroutines 8 ⟩ +≡

```

subroutine reverse_polygon( $n$ ,  $x$ )
  implicit_none_f77
  implicit_none_f90

  integer  $n$     // Input
  real  $x_{0:n,g2\_x:g2\_z}$ 
  integer  $i$     // Local
  real  $x\_temp_{g2\_x:g2\_z}$     /* This should work for both even and odd  $n$ . */

  do  $i = 0, (n - 1) / 2$ 
     $x\_temp_{g2\_x} = x_{n-i,g2\_x}$ 
     $x\_temp_{g2\_z} = x_{n-i,g2\_z}$ 
     $x_{n-i,g2\_x} = x_{i,g2\_x}$ 
     $x_{n-i,g2\_z} = x_{i,g2\_z}$ 
     $x_{i,g2\_x} = x\_temp_{g2\_x}$ 
     $x_{i,g2\_z} = x\_temp_{g2\_z}$ 
  end do

  return
end

```

## 29 Find endpoints in a set of elements

This routine examines a set of DG-type elements (*poly-elements*, consisting of  $n$  elements), presumably connected, to find the nodes belonging to a single element, i.e., the endpoints of the element chain. The number of endpoints *num\_ends* is returned, as are the corresponding node numbers (*end\_nodes*), pointers into the input *poly-elements* list (*end\_elements*), and tips of those elements (*end\_tips*).

⟨ Functions and subroutines 8 ⟩ +≡

```

subroutine find_endpoints(elements_list, n, poly-elements, num_ends, end_nodes, end_elements,
    end_tips)
    implicit none f77
    implicit none f90

    integer n    // Input
    integer elements_list*, element_start:element_end, poly-elementsn

    integer num_ends    // Output
    integer end_nodes*, end_elements*, end_tips*

    integer i, tip, test_node, match, j    // Local

    num_ends = 0
    do i = 1, n
        tip = element_start, element_end
        test_node = elements_listpoly-elementsi,tip
        match = FALSE
        do j = 1, n
            if ((j ≠ i) ∧ ((elements_listpoly-elementsj,element_start ≡
                test_node) ∨ (elements_listpoly-elementsj,element_end ≡ test_node))) then
                /* Should only be one match! */
                assert(match ≡ FALSE)
                match = TRUE
            end if
        end do
        if (match ≡ FALSE) then
            num_ends++
            end_nodesnum_ends = test_node
            end_elementsnum_ends = i
            end_tipsnum_ends = tip
        end if
    end do
    end do    /* Number of endpoints should be even! */
    assert((2 * (num_ends / 2) - num_ends) ≡ 0)
    return
end

```

## 30 Convert elements to a polygon

This routine transforms a set of DG-type elements, *poly\_elements*, into a linear list of points, a “polygon” as used elsewhere in this code, *poly\_x*, consisting of *poly\_num\_points*. The elements need not be all consistently oriented (i.e., so that each interior node is the “end” of one element and the “start” of another). But, the routine does expect to finish with a single chain (two endpoints) or a closed polygon. In the former case, the input pointer to the initial element (*initial\_element*) and tip (*initial\_tip*) must correspond to one of those endpoints.

**"definegeometry2d.f" 30 ≡**

**@m point\_loop #:**0

### 31 Count the number of continuous sections in set of elements

Namely, a set of elements should consist of one or more continuous sections, or curves. Some of these will be “open”, i.e., having two unmatched endpoints. The others will be “closed”. The primary objective of this routine is to find the latter. The routine returns the number of curves found and characterizes each as “open” or “closed”. For convenience, a second array identifies an element belonging to that curve, *curve\_start*. Another array labels each element according to the curve it belongs to.

(Functions and subroutines 8) +≡

```

⟨ Memory allocation interface 0 ⟩

```
gi_ext    /* Set up default sectors. These are taken to be at the interface between plasma / vacuum
    and solid / exit zones. The procedure consists of cycling through all of the segments of all of
    the polygons. The find_poly_zone routine returns all zones on both sides of this segment. In
    symmetric problems, there is just one on each side. In problems with resolution in the third
    dimension, more than one can appear on each side. When there are multiple entries on each
    side, the index for the third dimension in zn_index is used to identify zones in the same plane.
    find_poly_zone arranges for the type of zone1 to match that of the polygon. Then, sectors are
    defined at adjacent zones of different types. For example, a target sector is identified by having
    zone1 be a solid and zone2 be plasma. The target sector is then associated with zone1 (and its
    corresponding face, face1); zone1 is passed to define_sector as a check. */
