## 1    A Program for Defining 2-D Plasmas

This program is designed to be used in conjunction with **definegeometry2d**. Like **definegeometry2d**, the bulk of the data details are provided in one or more text files that can be generated by some other code. The data formats used here are sufficiently simple that they can also be produced manually. The specification of the “background” consists of two pieces:

1. The densities, velocities, and temperatures of the background (plasma) species. For simplicity, we will refer to these as the “plasma” species, even though in some problems, these species may be electrically neutral (e.g., for the purposes of studying neutral-neutral interactions).
2. A description of the neutral sources (e.g., recycling of a plasma flow onto a material surface).

As in **definegeometry2d**, the input file for **defineback** is not listed in **degas2.in**. Again, the reason is that this code is, in principle, just one of many different ways to provide background data to **DEGAS 2**.

The command line for the execution of **defineback** specifies the name of the main **defineback** input file. This file will contain pointers to other files that provide the plasma and source information.

**defineback an\_input\_file**

Like other text input files used in **DEGAS 2**, blank lines, spaces, and lines beginning with a comment character **#** are ignored (comments can also appear at the end of a line). This is true not only for the main input file, **an\_input\_file**, but also for the text files to which it refers.

## 2   Example Input File

Here is an example input file:

```
plasma_file mrx_plasma3
```

```
new_source_group
  source_type puff
  source_geom surface
  source_species D2
  source_root_sp D2
  source_nflights 1000
  specify_flux
  source_file mrx_source_2.in
end_source_group
```

```
new_source_group
  source_type puff
  source_geom surface
  source_species D2
  source_root_sp D2
  source_nflights 1000
  specify_flux
  source_stratum     1
  source_segment     *
  source_strength    1.e20
end_source_group
```

### 3 Plasma Data

This program contains by default a rather general mechanism for specifying the plasma data via a text file. The data can either be formatted in labeled columns or in more freely formatted rows. The ordering of the data in either case can match that of the zones or can be specified by a list of zone numbers.

There is essentially only one keyword associated with specifying the plasma data, `plasma_file`. The simplest form of this keyword, shown above, has only one argument, the name of the file containing the plasma data to be read in. In this case, the data in the file are assumed to be in the “tabular” format described below.

To use the alternative “row” formatting option, a second argument `row` must appear after the file name. E.g., for the example above,

```
plasma_file mrx_plasma3 row
```

An additional argument controls the specification of the plasma data in the third dimension of nearly symmetric 3-D cases (in which the *geometry\_symmetry* variable of `geomint.hweb` is *geometry\_symmetry\_plane.hw*, *geometry\_symmetry\_cyl.hw*, or *geometry\_symmetry\_cyl\_section*). The default assumption (i.e., that obtained without any additional argument to the `plasma_file` keyword) is that the plasma data are to be made symmetric in the third dimension. In these cases, the code expects the zone numbers provided to be those of the “reference zones” for which  $zn\_index(zone, zi\_ptr) = zone$ . As the plasma parameters are read in for these zones, the code will loop over the other zones pointing to them and assign them those same plasma parameters. Unless the user has set up the geometry so that these reference zones are numbered consecutively and beginning at 1 (`definegeometry2d` and `boxgen` currently do not do this when creating nearly symmetric 3-D geometries), the zone numbers should be explicitly listed.

If the plasma data are to vary in the third dimension in nearly symmetric 3-D cases, or if the user wishes to explicitly specify all plasma data, an added argument of `3D` can be added to the `plasma_file` keyword. E.g.,

```
plasma_file mrx_plasma3 row 3D
```

or, if the tabular format is to be used,

```
plasma_file mrx_plasma3 3D
```

The default behavior can also be obtained by setting this argument to `2D`.

There is also a keyword *plasma\_coords* allowing the user to specify the coordinate system of the plasma velocities as either *cartesian* or *cylindrical*. E.g.,

```
plasma_coords cylindrical
```

In two-dimensional problems, this choice is governed by the symmetry specified in `definegeometry2d`. As such, the user can ignore this keyword. It is provided only for completeness.

**Tabular Format** The key assumption for the tabular format is that all data pertaining to a particular zone are contained on a single line of the file. If the zone number is provided as the first number of a line, it will be used in assigning the data values on that line; in principle, any ordering of the zones could be used. Note that this zone number is the “absolute” zone, not the plasma zone number. If the zone number is not specified, the line number is used as the zone number. Problems having both the geometry and plasma data specified by some other code make this approach particularly simple.

A header line at the top of the file informs the code of the ordering of the data on each line. For example,

| zone | T(1)             | N(1)             | T(2)             | N(2)             |
|------|------------------|------------------|------------------|------------------|
| 1    | 1.0000000475e-03 | 1.0000000000e+01 | 1.0000000475e-03 | 1.0000000000e+01 |
| 2    | 3.0000000000e+00 | 3.0000000000e+19 | 3.0000000000e+00 | 3.0000000000e+19 |
| 3    | 1.0000000475e-03 | 1.0000000000e+01 | 1.0000000475e-03 | 1.0000000000e+01 |

Here, the first column contains the zone number. The second and third columns give the temperature and density of the first background species (referring to their ordering in the input file provided for **problemsetup**). The last two columns have the temperature and density for the second background species. Note that the assumed units are eV for temperatures and  $\text{m}^{-3}$  for densities.

Velocities (in meters per second) would be indicated by a string like **V2(1)** to indicate the velocity in the  $x_2$  (e.g.,  $y$ ) direction for the first background species. The columns may be in any order. The strings can be either lower or upper case (e.g., **ZONE** or **n(1)** would also be recognized). If particular data are not provided (such as the velocities in the above example), default values of 0 will be used.

Cases in which the plasma mesh has been created with the **sonnet\_mesh** or **uedge\_mesh** commands in **definegeometry2d** provide the best opportunity for simplifying the ordering of the plasma data in **defineback**. At present, the zones representing such a plasma mesh are defined in nested do loops according to:

```

zone=0
do ix=1,nx
  do iz=1,nz
    zone=zone+1
    .
    .
    .

```

where  $ix$  represents the first of the two indices used by **UEDGE** or **Sonnet** and  $iz$  represents the second. So, if the data are written out by looping over the  $iz$  index first, the zone number would not need to be specified.

If some other ordering we easier to generate, a separate column of zone numbers would be needed, computed according to  $zone = iz + (ix - 1)nz$ .

**Row Format** The tabular format can be easier to read, but more difficult to generate and manipulate. For that reason, a more loosely structured, row-oriented format is provided. Here's an example of such a file:

```
#
  N(1)
#
  2.17708e+18  2.34353e+18  2.67808e+18  3.02909e+18  3.40510e+18
3.81293e+18

1.77230e-19
  1.77150e-19  1.77062e-19  1.76967e-19  1.76863e-19  4.00000e-17
4.00000e-17
  4.00000e-17  4.00000e-17  4.00000e-17  4.00000e-17  4.00000e-17
4.00000e-17
  4.00000e-17  4.00000e-17  4.00000e-17  4.00000e-17  4.00000e-17
4.00000e-17
  4.00000e-17  4.00000e-17  4.00000e-17  4.00000e-17  4.00000e-17
4.00000e-17
```

These data are read in row-by-row. As in the tabular case, the default is that the data are listed according to zone number. If some other order is required, a list of zones can be provided *as the first item in the file*. The labels are parsed in the same way as those for the tabular format. Note that the labels actually serve as the delimiters for the data. That is, the reading routine will just keep reading row after row until it reaches another data label, so the data do not have to be formatted in any particular way (you can even have one data value per line - i.e., a single column of data). The only constraint is that there be no more than 136 characters on a line.

Again, the default unit for the temperature data is eV. The temperature can also be specified in joules. A units string indicating as much should be added to the label, as shown above. To avoid confusion, the code will also recognize “eV” as a units label for the temperature. *Note that this facility is currently not available for tabular data; those temperatures must all be in eV.*

**Non-default Plasma Data** The *get\_n\_t* subroutine that reads the plasma file has a simple, but flexible interface consisting of the string that follows the *plasma\_file* keyword in the **defineback** input file. As such, the user can easily replace this subroutine with a more sophisticated piece of code that can adapt available data to the geometry of a particular case. For example, some or even all of the plasma zones may be generated by **definegeometry2d**. If the user has some notion of the spatial variation of the plasma data, a specific version of the *get\_n\_t* subroutine can be written to map that description on to the **DEGAS 2** geometry using the internal geometry arrays that are available via the common blocks.

A more general implementation might pack several arguments into the string following the *plasma\_file* keyword. For example, the string might contain multiple file names, as well as integer and floating point parameters. The string would be parsed in whatever manner is desired (although use of **DEGAS 2**'s string manipulation routines is recommended).

An example of such a subroutine, used in work on the National Compact Stellarator Experiment (NCSX), is included here as an example. The version of the *get\_n\_t* subroutine to be used is controlled by file names. The default routine is contained in the file *def2dplasma.web*. A replacement routine will be loaded automatically by the **Makefile** if it is contained in a file named *usr2dplasma.web*. The NCSX example file is called *ncsxplasma.web*. In practice, one would use such a file by executing commands analogous to:

```
cd $HOME/degas2/src
cp ncsxplasma.web usr2dplasma.web
touch usr2dplasma.web
cd ../SUN
gmake defineback
```

Likewise, to revert to the default subroutine,

```
cd $HOME/degas2/src
rm usr2dplasma.web
touch def2dplasma.web
cd ../SUN
gmake defineback
```

Note the use of the **touch** command to make sure **gmake** recognizes the change.

The NCSX example shows how the stratum label available in **definegeometry2d** can be used to locate the zones generated by the triangulation of a particular polygon specified in a **definegeometry2d** input file. Namely, the polygons in the NCSX problem were drawn so that plasma parameters would be constant over them (they corresponded to magnetic flux surfaces); each of the polygons was assigned a unique stratum number. That information is available in the polygon netCDF file generated by **definegeometry2d** (the *g2\_polygon\_stratum* array); the zone numbers associated with each polygon are also there (in *g2\_polygon\_zone*). The two arrays are combined in this *get\_n\_t* subroutine to form a mapping array, *zone\_stratum*, that provides the stratum number associated with each zone. This then allows the subroutine to determine the plasma parameters to be assigned to those zones.

## 4 Time Dependence

The default and most frequently used mode of running DEGAS 2 simulates a steady state, time independent system; the time dependent mode of running DEGAS 2 is described more completely in the User Manual. Only two keywords are required in the *defineback* input file to enable time dependent operation: *time\_interval* and *source\_time\_variation*; the former is described below and latter in the next section with the other source group variables.

If a snapshot file is present from a previous time step, a new source group is automatically created by **defineback**; this will appear after the source groups directly specified by the user. **defineback** will compare the time associated with these particles against the value of  $t_{\text{init}}$  and print out a warning if they differ by more than roundoff error. The number of flights for the snapshot source group defaults to 100; the appropriate value for a particular run depends on the strength of the snapshot source relative to the other sources in the run. E.g., if they are comparable, the number of flights used should be as well. The user can change this value by editing the background netCDF file; that value will be retained for use in subsequent time steps.

To generate a snapshot distribution representative of an initial state (see the description in the User Manual), include the *time\_initialization* keyword at the top of the input file. The *time\_interval* and *source\_time\_variation* keywords should be set as they would be for the first step of the subsequent time dependent run.

The associated keywords have the form:

*keyword arguments*

*time\_interval*  $t_{\text{init}}$   $t_{\text{final}}$  specifies a time dependent run from  $t_{\text{init}}$  to  $t_{\text{final}}$  (in seconds) provided  $t_{\text{final}} > t_{\text{init}}$ .

If this keyword is not present, the run is assumed to be steady-state.

*time\_initialization* declares that the run will be carried out in the initialization mode for the purpose of generating a snapshot distribution. To have an effect, *time\_interval* must also be specified.

## 5 Source Group Data

The rest of the input file describes the sources to be used in the run. As the above example input file shows, each source group is specified in its own section. The specification is begun with a *new\_source\_group* command and ended with *end\_source\_group*. The order of the keywords in between *should not* matter.

For very simple sources (e.g., consisting of a two or three source segments), the requisite data can all be specified explicitly in the **defineback** input file. In other cases, only the “global” parameters for the source group appear in the **defineback** input file, and the segment-dependent data (*source\_stratum*, *source\_segment*, and *source\_strength*; in nearly symmetric 3-D cases, also need *source\_segment\_iy*) are placed in a separate file pointed to by the *source\_file* keyword. This option also permits the specification of local plasma data that can be used in the case of a plasma recycling flux to compute the sheath potential or even the magnitude of the flux. As in the plasma data files, both tabular and row formats are permitted for the source files.

The minimum specification of a volumetric source, *source\_type* **vol\_source**, requires a zone, a strength, and a temperature; a drift velocity can also be specified. For this reason, its parameters must appear in an external *source\_file* in row format with labels analogous to those of a plasma data file. No species or “back” index is required since a source by definition applies to only one species. Because a zone number completely determines the location of the source in the problem, *stratum*, *segment*, or *segment\_iy* values are not needed.

Each of the keywords (in *italics* occupies a line of the form:

*keyword arguments*

with some keywords having multiple arguments, others having none at all. Lower case single letters (perhaps with subscripts) are used to represent integer arguments. Upper case single letters correspond to real (i.e., floating point) arguments. All other arguments are strings.

*source\_type* **typ** gives the type of the source. The only types currently treated in DEGAS 2 are **typ = plate**, **puff**, **vol\_source**, **plt\_e\_bins**, **snapshot** and **recomb**. The last two are not needed in a **defineback** input file since a recombination source is established automatically by the inclusion of the appropriate reaction in the **problemsetup** input file. A snapshot source is set up automatically in a time dependent run if a *snapshotfile*, generated at the end of the previous step, is present.

The **plt\_e\_bins** source type allows the user to specify the energy distribution for the recycling ions via the additional parameters *source\_e\_bin\_num*, *source\_e\_bin\_min*, *source\_e\_bin\_max*, and *source\_e\_bin\_spacing*. The four parameters only describe the grid on which this distribution is specified. Since this energy distribution can vary from one segment to the next within this source group, the total number of parameters required to specify all of these distributions can be quite large. As such, they can only be input via the **row** option of *source\_file* (**E\_bin\_prob** and variants).

*source\_geom* **geom** specifies the geometry of the source. The most frequently used value is **geom = surface** (e.g., a line in a poloidal plane of an axisymmetric torus). Obviously, for a volume source **geom = volume**. Note that there is no default set, so *source\_geom* must be included with each source group.

*source\_species* **sym** determines the species to be generated by the source. This species must be in the list of test species for the problem. The **sym** is the species symbol that appears in the *species\_infile*.

*source\_root\_sp* **sym** determines the species underlying the source. For a *plate* source, this would be the ion corresponding to the neutral *source\_species*. For a **puff** or **vol\_source** source, this would be the same as *source\_species*. The code currently requires that *source\_root\_sp* be specified.

*source\_nflights*  $n_{\text{flights}}$  overrides a default value of 100 flights per source group. This keyword allows the user to avoid having to edit the background netCDF file to set the number of flights.

*source\_puff\_temp*  $T$  specifies the temperature  $T$  of a puff type source in Kelvin. If not set, a default value of 300 K will be used.

*source\_puff\_exponent*  $\alpha$  specifies the peakedness of the angular distribution of a gas puff. Namely, the puffed particle velocities will have angles  $\theta$ , the angle relative to the surface normal, distributed according to  $\cos^\alpha(\theta)$ . The default value is 1, although values as large as 2.5 are reasonable [e.g., see B. Farizon et al., *Nucl. Instrum. Meth. Phys. Res. B* **101** (1995) 287].

*source\_e\_bin\_num*  $n_{\text{bins}}$  is the number of bins used to specify the energy distribution at each source group segment in the **plt\_e\_bins** source type. The default is 4; the maximum value is *so\_e\_bins\_num\_max*.

*source\_e\_bin\_min*  $E_{\text{min}}$  is the minimum energy in eV of the energy distribution to be specified with the **plt\_e\_bins** source type. This value represents the “left edge” of the first bin. The default value is  $E_{\text{min}} = 1$  eV.

*source\_e\_bin\_max*  $E_{\text{max}}$  is the maximum energy in eV of the energy distribution to be specified with the **plt\_e\_bins** source type. This value represents the “right edge” of the  $n_{\text{bins}}$ -th bin. The default value is  $E_{\text{min}} = 10^4$  eV.

*source\_e\_bin\_spacing* **spacing** specifies the spacing of the energy distribution used with the **plt\_e\_bins** source type. The only supported values are: **spacing = linear**, which results in an energy distribution evenly spaced over  $n_{\text{bins}}$  between  $E_{\text{min}}$  and  $E_{\text{max}}$ , and **spacing = log**, which results in an energy distribution evenly spaced over  $n_{\text{bins}}$  between  $\ln(E_{\text{min}})$  and  $\ln(E_{\text{max}})$ . The default value is **spacing = log**.

*source\_time\_variation* **varn** specifies the time dependence of the source in time dependent runs. The only supported values are: **varn = delta** causes all source particles to be launched at time  $t_{\text{init}}$  (see *time\_interval* above), and **varn = uniform** causes the initial times of the source particles to be uniformly distributed between  $t_{\text{init}}$  and  $t_{\text{final}}$ . The default value is **delta**. More complex time variation can be obtained by discretizing the time variation of the source into a sequence of intervals, each with approximately constant strength.

*specify\_flux* informs the code that the *source\_strength* will represent a flux of particles (particles per square meter per second). This is the default. For a volume source, it's particles per cubic meter per second. In time dependent runs, this just becomes particles per square meter or per cubic meter.

*specify\_current* informs the code that the *source\_strength* will represent a current of particles (particles per second). In time dependent runs, this is just particles.

*source\_stratum*  $i_1 i_2 i_3 \dots$  is used together with the *source\_segment* and *source\_strength* keywords to explicitly specify the location and strength of a number (preferably a small number) of source surfaces. These three keywords must all have the same number of arguments. The keywords and their arguments have no preferred order. The value of *source\_stratum* corresponds to the *strata* associated with a sector, e.g., as assigned with the *stratum* keyword in **definegeometry2d**.

*source\_segment*  $i_1 i_2 i_3 \dots$  identifies which segments of the stratum specified by *source\_stratum* are to be used. If the *stratum* values have been chosen judiciously in running *definegeometry2d*, the user should be able to infer the desired segment values by counting off the segments of the corresponding polygon in the *definegeometry2d* input file (with the first side of the polygon being segment 0, the second 1, etc.). If all of the segments of a stratum are to be used, with the same source strength, a single wild-card argument of **\*** can be given with *source\_segment*; *source\_stratum* and *source\_strength* should have only one argument in this case.

*source\_segment iy i<sub>1</sub> i<sub>2</sub> i<sub>3</sub> ...* identifies the segments' third dimension label in nearly symmetric 3-D cases (in which the *geometry\_symmetry* variable of **geomint.hweb** is *geometry\_symmetry\_plane.hw*, *geometry\_symmetry\_cyl.hw*, or *geometry\_symmetry\_cyl\_section*). These labels correspond to the integer indices associated with the third dimension discretization set up in **definegeometry2d**. There, the user defines  $n_y$  surfaces in the third dimension (not counting those that define the universal cell). The resulting zones have  $i_y$  labels ranging from 0 to  $n_y - 2$ .

By default, all (i.e.,  $n_y - 1$ ) of the sectors having the specified *source\_stratum* and *source\_segment* are included. If this is the user's intent, the *source\_segment iy* keyword should not appear; a wildcard argument (e.g., **\***) cannot be used. The specified source current will be divided equally amongst these segments.

If the  $i_y$  values are specified, the user is effectively describing a source segment by three labels: the stratum, the segment number, and the  $i_y$ . Each such triplet will be assigned the corresponding source current (via the *source\_strength* keyword).

*source\_strength S<sub>1</sub> S<sub>2</sub> S<sub>3</sub> ...* gives the source strength (with units determined by the appearance of either the *specify\_flux* or *specify\_current* keywords) to be used in conjunction with *source\_stratum* and *source\_segment*.

*source\_file filename format* is an alternative method of specifying the location and strength of the source (i.e., in lieu of using *source\_stratum*, *source\_segment*, and *source\_strength*). The file **filename** is a text file of the usual type in which blank lines and comment lines beginning with **#** are ignored. The tabular and row-oriented formats available for these files are described below. The optional **format** argument should be set to **tabular** or **row**, respectively; the default is **tabular**.

**Tabular Format** The tabular format is somewhat restrictive. Unlike the analogous option for the plasma data, no header line is needed. Each line specifies a source segment:

$i_{\text{stratum}} \ i_{\text{segment}} \ S_{\text{strength}}$

That is, the stratum and segment numbers followed by its strength. This is the only permissible order for the three parameters. No wild cards are allowed. The units of the source strength are determined by which of *specify\_flux* and *specify\_current* is in effect. The third dimension  $i_y$  label has not been implemented for nearly symmetric 3-D cases. All sectors having the specified  $i_{\text{stratum}}$ ,  $i_{\text{segment}}$  value will be included, and the source current will be divided evenly amongst them.

When the source group is processed (following the *end\_source\_group* command), the code will print out the endpoint coordinates (only  $x$  and  $z$ ) of the sector associated with each source segment to provide the user with feedback on their specification.

**Row Format** The row format appears to be the more attractive option for the user because of its greater flexibility. For this reason, efforts to extend this code’s functionality have focussed on it. Roughly speaking, the format is the same as that of a row-oriented plasma data file; only the labels used will differ.

The simplest form for a “surface” geometry source file would have sections for the stratum number (using the label **stratum**; the code will also recognize **STRATUM** and **Stratum**), the stratum segment number (**segment**; the alternative capitalizations will also work), the segment  $i_y$  label (**segment\_iy**, etc.; for nearly symmetric 3-D cases; see the above description of the *source\_segment\_iy* keyword for additional details) and source strength (**f** or **F**; “f” stands for flux, although the meaning of the data provided is determined by which of *specify\_flux* and *specify\_current* is in effect).

A volumetric source (*source\_type vol\_source*) is simpler, needing only a zone (labels: **zone**, **ZONE**, or **Zone**), a strength (labels **f** or **F**; the meaning again determined by which of *specify\_flux* and *specify\_current* is in effect), a temperature (labels **t** or **T**), and perhaps a drift velocity (e.g., **v1** or **V1**). No stratum, segment, or segment  $i_y$  are required.

Fluid plasma codes usually maintain plasma data in small zones directly adjacent to the target for the purpose of setting boundary conditions. The zones are too small to merit direct inclusion in the neutral transport simulation. However, the data contained in them can be used for a recycling source to compute the local sheath potential or even the plasma flux.

**Sheath Model** When *defineback* sets up the segments of a plate source it will set the parameters for the sheath model; these are stored as miscellaneous source parameters, with the macro identifiers listed below. If specific plasma data for the sector are not specified (as described below), provided the electron temperature in the plasma zone adjacent to the source sector is positive, it will set *so\_param\_e\_ion\_delta* =  $3T_e$  (explicitly assuming that electrons are the first background species), leaving *so\_param\_e\_ion\_mult* set to 1. In this case, the  $3T_e$  represents a simple value for the sheath potential. If it so happens, e.g. in testing,  $T_e \leq 0$ , then *so\_param\_e\_ion\_delta* is set to 3 eV.

If specific plasma parameters are available for the source sector, such as those computed by a fluid plasma code for the purposes of setting boundary conditions, they can be included in a row-oriented source file. The same types of labels used for the plasma density, temperature, and velocity in a plasma data file will be recognized. The difference, of course, is that the values will correspond to the source segments, rather than to zones.

The sheath model currently in use needs only the electron temperature  $T_e$ , the temperature of the source ion  $T_i$ , and the source ion species’ flow velocity vector  $\vec{v}_i$ . The result is a value for the incident ion energy  $E_i$

$$E_i = 3T_i + \left(\frac{1}{2} + \phi\right) T_e, \quad (1)$$

$$\phi = -\ln \left( \frac{\sqrt{2\pi} |\vec{v}_i|}{\sqrt{T_e/m_e}} \right) \quad (2)$$

Since the model depends on only the magnitude of the flow velocity, *defineback* will also proceed to evaluate these expressions if just the parallel velocity (labeled by **v\_par**) is provided. The result is placed into the *so\_param\_e\_ion\_delta* entry and the corresponding *so\_param\_e\_ion\_mult* entry is set to zero.

**Plasma Flux Computation** The strength of the source can be computed directly by **defineback** if the requisite data are provided in a row-oriented source file. In this case, there is no need to explicitly specify the strength of the source in the input file(s) (more precisely, if a strength is specified, the flux will not be computed).

The code will need:

1. The source ion density, e.g., labeled **N(2)**,
2. The source ion *parallel* velocity, e.g., labeled **v\_par** (also, **V\_PAR**, **V\_Par**, etc.),
3. The *parallel* (i.e., taking into account the field line pitch and angle of incidence on the surface) area, e.g., labeled **Area** (also **area** or **Area**).

The *specify\_current* option needs to be given to prevent the perpendicular area from being factored in when the internal source arrays are loaded. As noted above, if the electron temperature is also provided, the code will evaluate the incident ion energy using Eqs. (1) and (2).

**Binned Energy Distribution** Note first that this energy distribution characterizes the particles as they strike a material surface, not at the sheath entrance. I.e., the particles will not be accelerated through the sheath, and there is no need to specify parameters for the sheath.

The only quantity specified in the *source\_file* is the relative probability of the distribution over the  $n_{\text{bin}}$  (*source\_e\_bin\_num*) bins, labeled with **E\_bin\_prob** (or **E\_BIN\_PROB**, **e\_bin\_prob**). From this distribution, **defineback** will compute a normalized, cumulative distribution suitable for sampling during the run of the main code.

The primary difference between this and other quantities in the *source\_file* is that there are  $n_{\text{bins}}$  parameters for each source segment. These will be read in from the file with the first  $n_{\text{bins}}$  numbers assigned to the first segment, the second  $n_{\text{bins}}$  to the second segment, etc. As with the other quantities, the data are read in one row at a time. The user is otherwise free to arrange these data in whatever manner is convenient or most readable.

**Additional Comments on Source Locations** The stratum is just the stratum label assigned in the **definegeometry2d** input file to the polygon that contains the solid surface that the source ions will be striking. This number should be the same for all of the elements of each source group. The segment number is determined by the location of that solid surface within the list of polygon points. One way to automate the setting of the segment number is to arrange the polygon points in the **definegeometry2d** input file so that the first points in the polygon are the ones that will be used as source segments. Then, you'll know that the segment number goes from 1 to the desired number of segments. Note that for **definegeometry2d** to keep track of the segment numbers, the polygon has to be specified in a clockwise direction. An alternative approach would be to define an auxiliary stratum for each source group consisting of just the desired segments. Again, the segment numbers would just range from 1 to the number of source segments.

**Screen Output from Source Group Processing** As *defineback* processes each source group, it will print to `stdout` information on each segment of that group. For example:

```
Processing source group   1

  source          stratum segment          sector points
  segment stratum segment   iy          x1    start    x3
x1    end      x3
  1          7      50        0          5  1.59600E+00  1.45000E-01
1.59600E+00  1.40000E-01
  2          7      52        0          7  1.59600E+00  1.55000E-01
1.59600E+00  1.50000E-01
  3          7      49        0          9  1.59600E+00  1.40000E-01
1.59600E+00  1.37600E-01
⋮
```

Obviously, the first line identifies the source group number. The items in the table are

**source segment** This is the running count of segments in this source group. It can be used subsequently to identify this segment in the background `netCDF` file, when running the code in a debugger, or when using the *sourcetest* code. Note that this ordering may not (occasionally it may) correspond to the order of the source segments listed in the input file(s) provided to *defineback*. The other output columns can be used to relate the two lists.

**stratum** Is the stratum label of the source sector (i.e., *strata<sub>sector</sub>*). This corresponds to the “stratum” value specified in the input file.

**stratum segment** Is the stratum segment label of the sector (i.e., *sector\_strata\_segment<sub>sector</sub>*). This corresponds to the “segment” value specified in the input file.

**segment iy** Used only for 3-D cases, this is the  $i_y$  value of the zone associated with this sector and corresponds to the “segment\_iy” value specified in the input file.

**sector** Is the geometry’s *sector* number for this source segment.

**sector points** Provides the “start” and “end” points contained in the *sector\_points* array for this *sector*. Presently, the “x2” coordinate is not used (even in 3-D cases; the  $i_y$  value effectively provides that information).

## 6 Iterative Problems

This code is now capable of being used in conjunction with the **UEDGE** plasma code (via the version of subroutine *get\_n\_t* in the file **uedgeback.web**). Moreover, the ability to iterate between **UEDGE** and **DEGAS 2**, previously available only with **readbackground** and **updatebackground** has been incorporated. None of the code in **defineback** is **UEDGE**-specific, however. Establishing an analogous iterative capability with another code would involve replacing just the *get\_n\_t* routine.

Three different indicators inform **defineback** that it is being used in this iterative fashion.

1. The *iterative\_run* keyword appears at the beginning of the **defineback** input file. This keyword needs no arguments; it confirms the user's intention to pursue an iterative solution.
2. An **oldsourcefile** is present; the actual filename is specified in the **degas2.in** file. This file contains the values of the source "class" data (currents and weights) from the initial run of **defineback** in an iterative run; i.e., this file gets written out only if the *iterative\_run* keyword has been invoked and if a name has been specified for it. Likewise, it is read in on a subsequent ("update") run if the **oldsourcefile** has a name and is present; otherwise, **defineback** will *not* run in update mode.
3. The number of source groups *so\_grps* is greater than zero when the *get\_n\_t* subroutine is called. Directly informing the *get\_n\_t* subroutine that **defineback** is running in "update" mode would require modifying its argument list. Instead, we use the value of *so\_grps* as a proxy. When the **oldsourcefile** is read in, it sets *so\_grps* to its value from the previous invocation of **defineback**. This value reaches the *get\_n\_t* subroutine via the source "class" data.

The consistency of these three flags is checked. The most detailed checks are on the members of the source "class" that should remain the same from one iteration to the next. In particular, the current value of *so\_grps* is required to be the same as that obtained from the *oldsourcefile*; the same is true for the number of source segments and their locations within the geometry.

By storing the initial source data in the **oldsourcefile**, changes in the source current distribution on subsequent iterations can be accounted for by weighting factors [see: D. P. Stotler et al., *Contrib. Plasma Phys.* **40** (2000) 221]. This is a form of correlated sampling. After some number of iterations, the distribution will have changed enough that this approach becomes ineffective. The parameters used to control this decision are *so\_rel\_wt\_min* and *so\_rel\_wt\_max*. The sampling arrays are then recomputed and the **oldsourcefile** over-written. Note that if an **oldsourcefile** filename is specified, **defineback** will look for that file. If it exists and can be read, **defineback** will assume that it is being invoked to update the plasma and source data as was just described. Hence, the user needs to delete an existing **oldsourcefile** before the initial run of **defineback**. On the other hand, if the **oldsourcefile** filename in **degas2.in** is not specified, the iterations will proceed, but without the benefits of this weight rescaling.

A detailed description of the procedure used to couple **DEGAS 2** and **UEDGE** is provided in **uedge-degas2-coupling.pdf** in the **degas2/Doc** directory.

## 13 Parse tabular plasma data header

This routine takes the text description of the plasma data format provided by the user and translates it into an integer code that can be more readily used in reading the data. This additional step also facilitates testing the format. One additional capability simplifies the specification of data for a large number of background species.

## 14 Read row-oriented plasma data

This is analogous to the default routine, but the data are arranged in rows rather than in columns. Again, if zone number data are provided, they are used to control the ordering of the data values. If not, the data are assumed to be arranged by ascending zone number. The data are read using DEGAS 2's string-handling routines, giving the user flexibility in the appearance of the data. This also permits the user to provide fewer data values than zones, if desired.
